

# **SCI-WMS: A Python based Web Mapping Service for Visualizing Geospatial Data**

Brandon A. Mayer, Brian McKenna, Alexander Crosby and Kelly Knee

**Abstract** SCI-WMS [1] is an open-source python implementation of an OGC WMS service [2] for qualitatively assessing society-critical atmospheric and oceanographic applications including forecasting, risk assessment, model comparison and algorithmic/parameter selection. The modular cross-platform implementation of SCI-WMS allows the service to keep pace with the rapid developments in the geospatial data science community and to produce visualizations for numerous types of model outputs with transparent support for both structured and unstructured geo-referenced topologies. This article outlines the implementation and technology stack for visualizing geospatial Climatological and Forecasting (CF) data using SCI-WMS and details the deployment of SCI-WMS for visualizing model data and simulations within the scope of the U.S. IOOS Coastal and Ocean Modeling Testbed project [3].

## **1 Motivation**

Due to the explosion in the amount of atmospheric, oceanographic, climate and weather data, either recorded *in-situ* or generated by modeling, inference or prediction algorithms, it is no longer feasible for a single institution to host and maintain a centralized datastore. Modern data management has been shifting hosting and maintenance responsibilities of large datasets to multiple participating institutions unified by a catalogue service to provide a single, unified view of the distributed data to end users and analysts.

A common practice is for data producing organizations to host their own data which is exposed to the catalogue service via a particular communication protocol. The institution responsible for maintaining the catalogue then provides a unified view of the aggregated dataset to end users by compiling meta data associated with the participating organizations and registered data. Such federated datasets may span petabytes of geospatial information, be composed of millions of files in different formats generated and hosted by vastly different systems located across the globe. Additionally, the catalogue can grow or shrink as new datasets or participants are added and removed from the federation. By interacting with the catalogue, the end user (such as an analyst) can navigate and search through the aggregated meta data and interact with particular data of interest, agnostic to distributed nature of the database.

While a decentralized approach to data management offers many advantages such as robustness to failure (a failure at any one organization only effects the data associated with that organization), data reduction and analysis tools have been slower to adapt to the new framework. For example, there are an abundance of applications for visualizing cartographic data on a single computer or clusters. However, many such programs are designed to deal with data saved in a particular *local* file format, requiring analysts to download a local copy datasets, potentially reformat the data into the appropriate container before processing and analysis may begin. This paradigm implicitly assumes every potential end user has the resources to copy and process a potentially massive amount of data, which is not always the case. Even if an analyst has access sufficient resources, tools operating on local systems increase the project costs in terms of bandwidth usage, time and storage. Additionally, coupling decentralized storage and local processing introduces the risk that different analysts working with identical local copies of data obtained from the same federation may use different local programs to generate incompatible visualizations or conclusions. Normalizing these results introduces a potential point of error and likewise increases the costs of analysis in terms of time and accuracy. The local analysis paradigm violates the ethos of distributed data storage as the goal of a federated project is to minimize data redundancy. Therefore, data processing and visualization software must adapt to the imposed distributed memory model to likewise to realize the same benefits.

SCI-WMS is a web service designed to solve many of the aforementioned problems. By maintaining a list of web accessible endpoints, SCI-WMS is able to transparently produce consistent visualizations of federated data. While SCI-WMS implements the OGC WMS protocol, it is augmented with services for interacting with standard meta-data catalogues such as CSW [4], allowing SCI-WMS to autonomously track dynamic federations.

SCI-WMS uses NcML (NetCDF Markup Language) to implement a data abstraction layer. This allows data hosting agencies to maintain their own environments and file formats which are exposed to SCI-WMS without writing custom i/o software or replication and reformatting of information. Additionally, SCI-WMS is CF-Compliant [5], offering consistent views of endpoints which adhering to the CF-Metadata conventions embedded in the NcML file.

SCI-WMS embraces distributed database principles and promotes the separation of concerns software and project management practice. SCI-WMS may be deployed by a member of a much larger project who's sole responsibility is providing a visualization platform, promoting quality through specialization. Additionally, SCI-WMS saves costs for data analysis projects by providing a simple interface for end users to generate consistent visualizations of federated data. Perhaps more importantly, the introduction of a single web-based visualization service for distributed datasets ensures qualitative assessments and conclusions are made on equal footing regardless of analyst or data origin and is one of the first services for visualizing geospatial data associated with an unstructured topology.

## 2 SCI-WMS

### 2.1 Overview

SCI-WMS is an open-source implementation of the Open Geospatial Consortium's (OGC) Web Map Service (WMS) standard which specifies an HTTP interface for generating rasterized visualizations of geospatial data [2]. More specifically, WMS defines a RESTful API which responds to standardized HTTP GET requests from a web client. A typical WMS request specifies a data layer and region of interest with optional meta data such as rendering style parameters. A WMS response may include additional meta data providing information about data registered with the service or a visualization (commonly a PNG or other standard image format) of a particular data layer for display by the front end web client.

SCI-WMS is implemented in Python using the Django [6] web framework and standard cross-platform numerical software, NumPy [7] and Matplotlib [8] for generating visual content. Additionally, the open-source python implementation provides a cross-platform WMS solution which can leverage the suite of tools developed by the geospatial data analysis community, such as pyugrid [9], to maintain pace with the latest geospatial software and standards developments including unstructured grid support and CF-UGRID Compliance [10].

While the OGC WMS specification standardizes the client-server communication protocol, WMS implementations free to design that fulfills WMS requests and responses. Vital to the efficiency of SCI-WMS is the abstraction of a registered dataset into structure (also known as topology) and attributes as shown in figure ?? and detailed in subsequent sections. SCI-WMS maintains a local topology cache for efficient storage and processing of spatial neighborhoods and subsets with respect to data structure. For storage efficiency, attributes are not replicated locally but referenced via OGC compliant web-services and a database of structure-endpoint pairs is maintained as visualized in figure 1b. Because geospatial WMS requests are commonly restricted to a subset of the Earth's surface, SCI-WMS uses the topology cache to compute the subset of model data needed to fulfill each request prior to re-

trieving the appropriate attributes (which are typically external to the server hosting SCI-WMS and accessed via HTTP). Furthermore, by classifying a topology as regular or irregular, efficient algorithms and data structures are exploited to optimize the computation of relevant model data subsets.

## 2.2 Dataset Abstractions

Visualization tools often decompose data into structure and attributes [11]. Due to the discrete nature of digital computers, any continuous function to be estimated must be sampled and measured at a discrete set of points. However, rendering a visualization typically requires knowledge of the values between the samples to produce a perceptually continuous images from arbitrary viewpoints. Structure encapsulates both the locations and connectivity relations onto which attributes are superimposed where connectivity serves to constrain the interpolation problem. Note that some authors further decompose structure further into topology and geometry [12], however, in the context of this research, topology is synonymous with the structure abstraction. Figure 1a outlines the data model adopted by SCI-WMS. A dataset is composed of attributes with associated structure that is further classified as a regular or irregular topology, known as c-grid and u-grid topologies in SCI-WMS documentation.

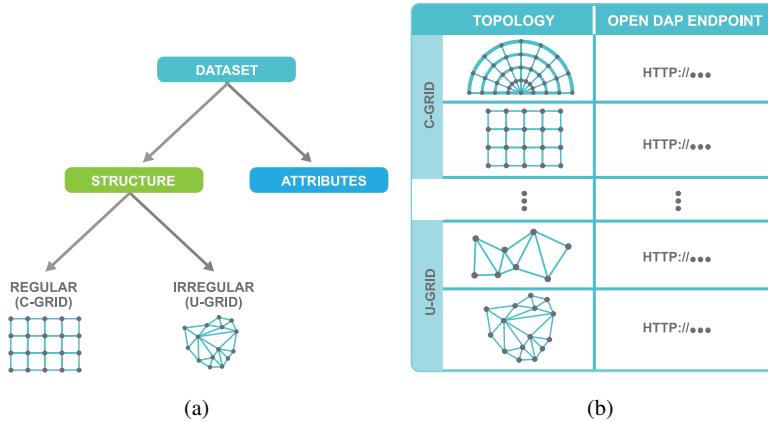

Fig. 1: (a) Decomposition hierarchy of the data model. A dataset submitted to SCI-WMS is decomposed into attributes and structure which is further classified as a regular (c-grid) or irregular (u-grid) topologies. (b) SCI-WMS topology and endpoint data store. Topologies are stored locally in implicit form for c-grid or binary R-Tree databases for u-grid topologies.

### 2.3 c-grid Topology

c-grid topologies refer geo-referenced locations and connectivity relations that can be defined analytically, e.g., rectilinear or curvilinear grids. Storing c-grid topologies amount to storing the closed-form expression. Algorithms for processing c-grids such as finding nearest neighbors or finding points that fall within a polygonal subset are computed directly using the implicit c-grid representation, incurring minimal computational overhead.

### 2.4 u-grid Topology

A u-grid topology is defined as a topology that is not regular, i.e., does not admit a closed-form representation. u-grid topologies offer the highest level of flexibility from a visualization and modeling standpoint as higher sampling frequencies may be used regions of interest while sparsely sampling low-impact areas.

Any NCML file which exposes the topology of an externally hosted dataset according to the CF-UGRID specification can be processed by SCI-WMS. According to the CF-UGRID standard, a topology is always embedded on the real line, in the plane or space with sample locations, the vertices of the topology, exposed as an array of coordinates in the appropriate ambient space. Vertex connectivity is expressed as a  $M \times D$  array where each element is an index into the vertex list. The dimension of a topology (equal to  $D - 1$ ) defines the atomic spatial element created by the connectivity list. In CF-UGRID terminology, a topology with dimension 0 defines a set of disconnected points (no connectivity) called *nodes*, a 1D topology consists of lines or curved boundaries known as *edges*, a 2D topology is a set of planes or surfaces enclosed by a set of edges (e.g. triangulation) called *faces*, and a 3D topology specifies the volume enclosed by a set of faces called *volumes*.

For example, figure 2b visualizes a list of a sample locations as an array of coordinates in the real plane. Topology connectivity is specified by a list of indices into the vertex array interpreted anticlockwise. Figure 2c visualizes a 2D connectivity list, defining a triangulation in the plane, for the vertex array in figure 2b where each entry is an index of the vertex list:  $v_n \in \{0, \dots, N - 1\}$ . Each row of the connectivity array defines a triangle: triangle  $m$  is specified by linking the coordinates associated with vertex lists by connecting  $v_m^0$  to  $v_m^1$  to  $v_m^2$  and back to  $v_m^0$ .

Figure 2a shows a u-grid 2D topology, a triangulation in the plane, used by a climate model for simulating hurricane conditions in the Gulf of Mexico. Vertices represent locations where attributes are estimated and the connectivity is shown as red lines connecting the vertices throughout the region of interest. The visualization was produced by accessing the CF-UGRID compliant NcML file. The u-grid topology allows the modelers to save storage and computational resources by sparsely sampling areas where accuracy can be sacrificed, such as the center of the Gulf, while allowing for higher sampling rates where accuracy is paramount, such

as densely populated coastal areas. However as shown, u-grid topologies require explicit enumeration of vertices and connectivity, and as such, require spatially-aware data structures for optimal storage and processing for performant visualization algorithms.

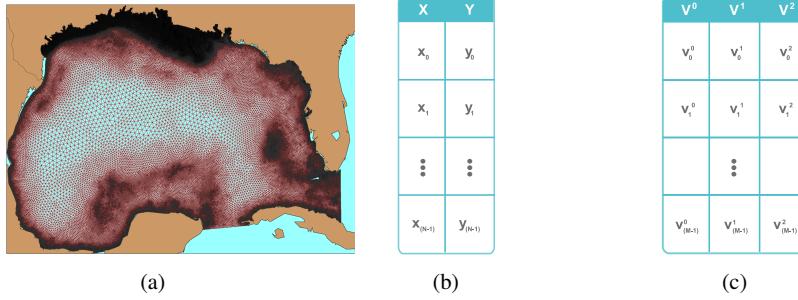

Fig. 2: Examples of an u-grid topology and CF-UGRIDcompliant vertex and connectivity arrays. (a) The location of  $N$  vertices in the real plane. (b) A 2D topology with  $M$  triangles. Each triangle represented as a row in the table referencing locations as indices into the vertex array.

## 2.5 Attributes

Attributes are defined as any numerical quantity associated with a set of samples, regardless of the classification of the underlying topology. For example, an atmospheric model may estimate wind direction at the vertices of a triangulated 2D topology or may compute air temperature at the centroid of cell volumes specified by a 3D topology. Additionally, attributes maintain their own dimensionality. An attribute specifying temperature or sea-surface-height would consist of scalar attributes while wind directions are vector valued and tensor valued attributes are also possible.

## 2.6 Distributed Memory Model

SCI-WMS decomposes an externally hosted dataset into a structure (topology), defined as a geo-referenced spatial set of sample locations and connections, with associated attributes.

Fulfilling a WMS request requires computing visible regions of a topology, fetching attributes and using connectivity information to produce an accurate rendering. The most computationally expensive operation in this pipeline is determining the

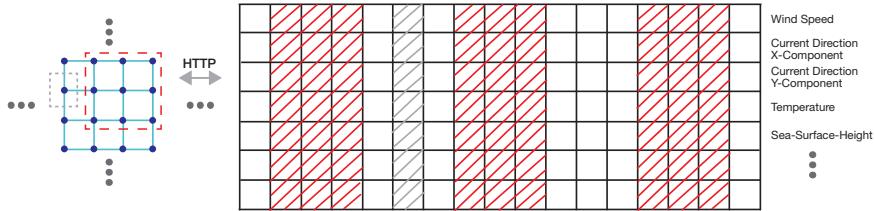

Fig. 3: SCI-WMS distributed memory model.

minimal amount of attributes needed to be fetched for processing for a given visualization request. To this end, for every dataset with an underlying u-grid topology, SCI-WMS maintains a binary R-tree stored locally to the SCI-WMS deployment server for fast access and processing.

After

For example, atmospheric and oceanographic models typically define a fixed topology covering a particular spatial extent of the earth. A model will estimate attributes of interest such as sea-surface-height, wind or current magnitudes and directions. The topology of the model encapsulates the positions and connectivity of the dataset for which attributes are associated. Visualizations of datasets are typically restricted so some region of interest, a subset of the available topology and a single attribute such as current direction. It is therefore paramount to the efficiency of visualization software to represent topologies in such a way as to optimize topology storage and reduction algorithms to facilitate efficient attribute retrieval.

To this end, when a dataset endpoint is submitted to SCI-WMS, the topology of the underlying endpoint is stored locally to SCI-WMS and a database of topology-endpoint associations are maintained as visualized in Figure 1b.

### 3 Deploying SCI-WMS for the U.S. IOOS COMT Testbed

While SCI-WMS is a general software solution for geospatial visualization, it is a key component in realizing the U.S. IOOS COMT mission, facilitating qualitative model comparisons and aggregation through a unified visualization framework. Figure 4 outlines the cyberinfrastructure behind the deployment of SCI-WMS for the COMT project.

The U.S. Integrated Ocean Observing System (IOOS) Coastal and Ocean Modeling Testbed (COMT) was formed to unify otherwise disparate entities in government, academia and industry to leverage the proliferation of oceanographic data and modeling techniques to combat natural and man-made coastal stressors by accelerating the turnaround from research and development to operational application of society-critical applications including: forecasting, model comparison, model skill assessment, and algorithmic/parameterization improvements [3]. Key to the U.S.

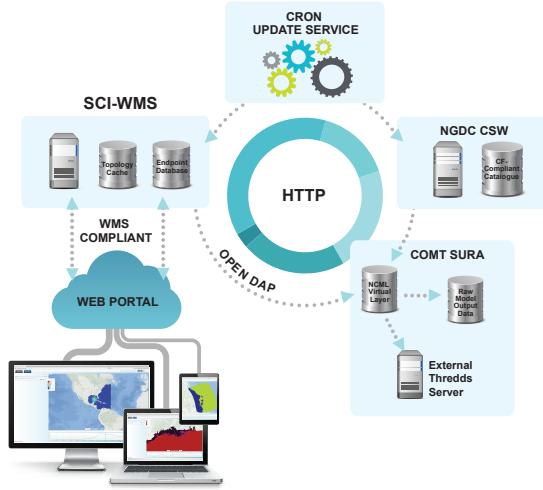

Fig. 4: Overview of the SCI-WMS deployment for the U.S. IOOS COMT project. SCI-WMS updates its topology and endpoint database via a nightly service which queries CF-Compliant datasets cataloged by NGDC. Model data is hosted on an external web server exposed by an NcML facade as a single NetCDF data structure accessible to SCI-WMS via OPeNDAP. SCI-WMS responds to http clients interfacing through a custom built web portal.

IOOS COMT mission is an extensible and universally available tool for quickly visualizing and assessing a diverse set of coastal modeling data. SCI-WMS is a general OGC WMS solution for serving rasterized visualizations of geospatial data which has been deployed for the COMT project to provide visualizations of a wide range of scientific data.

The NOAA<sup>1</sup>–NGDC<sup>2</sup> Geoportal indexes public geophysical datasets and provides an OGC Catalogue Web Service (CSW) to query datasets by their metadata attributes. SCI-WMS queries the NGDC Geoportal at regular intervals updating both the topologies and OPeNDAP links for all new or modified datasets.

Raw coastal data is hosted by the Southeastern Universities Research Association (SURA) on a dedicated server for the COMT project [13]. Each data set may consist of multiple files in different formats, and may be the result of very different models run by various institutions with disparate computing resources. However, accompanying each dataset is an NcML virtual layer which exposes each dataset as

<sup>1</sup> National Oceanic and Atmospheric Administration

<sup>2</sup> National Geophysical Data Center

a single NetCDF object which may be accessed via OPeNDAP<sup>3</sup>. Furthermore, the NcML facade presents a consistent set of meta information in accordance to CF-Conventions [5] providing services like SCI-WMS access to the raw data through a uniform interface.

Currently, SCI-WMS is used to visualize data from the first phase groups of IOOS COMT program: *estuarine hypoxia, shelf hypoxia and coastal inundation* [3]. For each modeling group, SCI-WMS successfully generates visualizations from ADCIRC, FVCOM, SELFE and SLOSH models and serves as a use-case of how SCI-WMS can be leveraged as a scalable solution for delivering consistent visualizations of scientific data to a diverse community.

## 4 Results

Figure 5 shows a web portal utilizing the SCI-WMS backend to compare ADCIRC model output for Hurricane Ike with water levels observed by NOAA stations. On-going development is in progress for SCI-WMS to support emerging geophysical datasets such as ensemble model output and to provide clear visual support for the assessment and quantification of model skill and performance metrics.
